Spherical Dynamics of Atomic Gravity

Science are built from how we perceive our world. Knowledge are built by how we comprehend on how the world working and functions. We tries to decode the basic ground on matters, to have the right perspective of structures, dimension, aspects, characteristics, principles, constant and the dynamics in everything we saw, tested, synthesize, replicates, hypothesizes, and developed further.

The learning process are in the steps we took in creating applied equations that can solve everyday and future problems, to reach advancement on technology and social hypothesis. As our neuronics brain never stops to reaps new comprehension from our surroundings, even when we sleep. Cerebral functions in our brain are also never ceased to functions in processing the informations we have learnt in a day, to prepare us for handling more intricacies in any problems might occurring.

Learning starts when we open our heart to receive informations that we need to comprehend future matters. Communication starts when we try to understand and acknowledge the people we encounter, the person we met, the human we studies, the children we raise, the family we upbringing in, and the societies we are rooting and grounding at. To communicate is not about how to respons, or how to talk , but about how to understand, to listen, to have the right perspective when facing certain and uncertainty.

At the efforts of understanding the trillion microns level of the layers of spherics in our sub-atomic, whether it is perceives biologically, chemic, or physically, the angular atomic momentum theories was designed. We hope the equations here can be applied for engineering the future protonic gluon interaction dynamics, to open new frontiers of Micron Quantum Interactions Dynamicity Equation by founding applied logical multi science equations to decipher and decode future atomic developments.

Core Atomic Flux Measurements

HOW TO MEASURE THE ELECTRONIC AND MAGNETIC VIBRATIONS FLUX IN CORE ATOMIC MATTERS AT THE HADRON SCALE

Measuring electronic and magnetic flux vibrations at the atomic core and hadron scale requires advanced quantum sensing and high-energy physics techniques. At the atomic level, scanning tunneling microscopy with quantum sensors can detect single-electron and nuclear spin fields, while at the hadron scale, particle accelerators like CERN's LHC use harmonic coil systems and hadron yield fluctuations under magnetic fields to probe these phenomena.

Atomic-Scale Measurement Techniques

- Quantum Sensors (STM-based):
 - A single-molecule quantum sensor can be fabricated at the apex of a scanning tunneling microscope (STM).
 - By attaching Fe atoms and organic molecules (like PTCDA), researchers achieve single-electron spin sensitivity and detect faint magnetic fields at atomic resolution.
 - This allows measurement of electronic and magnetic vibrations directly at the atomic core level.
 - Applications: mapping spin states, probing quantum coherence, and studying electron-nuclear interactions.

Comparison of Techniques

Scale	Method	What It Measures	Example Application
Atomic Core	STM Quantum Sensor	Single-electron & nuclear spin fields	Mapping atomic spin states
Hadron Scale	Harmonic Coil System (LHC)	Fast-changing magnetic flux in dipoles	Accelerator stability
Hadron Scale	Yield Ratio Fluctuations	Magnetic field influence on hadron yields	Heavy-ion collision magnetometry

Core Atomic Flux Measurements

HOW TO MEASURE THE ELECTRONIC AND MAGNETIC VIBRATIONS FLUX IN CORE ATOMIC MATTERS AT THE HADRON SCALE

Hadron-Scale Measurement Techniques

- **Magnetic Flux in Accelerators (LHC):**
 - The Large Hadron Collider (LHC) uses harmonic coil magnetic measurement systems to quantify magnetic field harmonics in superconducting dipoles.
 - Fast-changing magnetic fields are measured with rotating units and high-bandwidth electronics, enabling precise monitoring of magnetic vibrations at hadron interaction scales.
- **Hadron Yield Fluctuations under Magnetic Fields:**
 - In heavy-ion collisions, external magnetic fields influence hadron yield ratios (e.g., proton-to-pion, neutron-to-proton).
 - These fluctuations act as a magnetometer, indirectly measuring magnetic flux effects at the hadron resonance gas scale.
 - Example: ALICE Collaboration at CERN observed centrality-dependent yield ratios linked to magnetic field strength.

Challenges & Limitations

- **Atomic scale:** Sensitivity limited by noise and quantum decoherence; requires ultra-low temperatures and vacuum.
- **Hadron scale:** Measurements are indirect (via yield ratios) and depend on collision models; magnetic flux in accelerators requires extreme precision.
- **Cross-scale gap:** Directly linking atomic vibrations to hadron-scale flux is still an open frontier in quantum chromodynamics (QCD).

Angular momentum theory in Core Atomic Angular Physics

The core of atomic angular physics revolves around the understanding of angular momentum, a fundamental property of motion in both classical and quantum mechanics. Angular momentum is conserved in isolated systems and is a key concept in the study of atomic physics and quantum problems involving rotational symmetry. It is defined as the vector sum of the individual angular momenta of a rigid body undergoing rotation. The angular momentum operator plays a central role in the theory of atomic physics and is essential for understanding the behavior of particles in quantum states.

Eigenvalue equation in polar coordinates

The classical definition of the angular momentum vector is

$$\mathcal{L} = \mathbf{r} \times \mathbf{p} \quad (3.1)$$

which depends on the choice of the point of origin where $|\mathbf{r}|=r=0$ if $r=0$. With the definition of the position and the momentum operators we obtain the angular momentum operator as

$$\hat{\mathbf{L}} = -i\hbar(\mathbf{r} \times \nabla) \quad (3.2)$$

The Cartesian components of $\hat{\mathbf{L}}$ are then

$$\hat{L}_x = -i\hbar(y\partial_z - z\partial_y), \quad \hat{L}_y = -i\hbar(z\partial_x - x\partial_z), \quad \hat{L}_z = -i\hbar(x\partial_y - y\partial_x) \quad (3.3)$$

One frequently needs the components of $\hat{\mathbf{L}}$ in **spherical coordinates**. In order to obtain them we have to make use of the expression of the position vector by spherical coordinates, which are connected to the Cartesian components by

$$\mathbf{r} = x\hat{\mathbf{e}}_x + y\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z = r \sin \theta \cos \phi \hat{\mathbf{e}}_x + r \sin \theta \sin \phi \hat{\mathbf{e}}_y + r \cos \theta \hat{\mathbf{e}}_z \quad (3.4)$$

Going over to the spherical components in (3.3), and using the chain rule:

$$\partial_x = (\partial_x r) \partial_r + (\partial_x \theta) \partial_\theta + (\partial_x \phi) \partial_\phi \quad (3.5)$$

and similarly for ∂_y and ∂_z gives the following components

$$\begin{aligned} \hat{L}_x &= i\hbar(\sin \phi \partial_\theta + \cot \theta \cos \phi \partial_\phi) \\ \hat{L}_y &= i\hbar(-\cos \phi \partial_\theta + \cot \theta \sin \phi \partial_\phi) \\ \hat{L}_z &= -i\hbar \partial_\phi \end{aligned} \quad (3.6)$$

One sees at once the reason and the advantage of using spherical coordinates: the operators in question do not depend on the radial variable r . This is of course also true for $\hat{L}^2 = \hat{L}_x^2 + \hat{L}_y^2 + \hat{L}_z^2$ which turns out to be $-\hbar^2$ times the angular part of the Laplace operator $\Delta_{\theta\phi}$.

$$\hat{L}^2 = -\hbar^2 \left(\partial_{\theta\theta}^2 + \cot \theta \partial_\theta + \frac{1}{\sin^2 \theta} \partial_{\phi\phi}^2 \right) = -\hbar^2 \Delta_{\theta\phi} \quad (3.7)$$

We shall now find the eigenfunctions of $\Delta_{\theta\phi}$, that play a very important role in quantum mechanics, and actually in several branches of theoretical physics. They will be functions of $0 \leq \theta \leq \pi$ and $0 \leq \phi < 2\pi$, i.e. they can be considered as complex valued functions whose domain is the unit sphere. The eigenfunctions of $\hat{L}^2$ will be denoted by $Y(\theta, \phi)$, and the angular eigenvalue equation is:

$$\begin{aligned} -\Delta_{\theta\phi} Y(\theta, \phi) &= \ell(\ell+1) Y(\theta, \phi) \quad \text{or} \\ \left(\partial_{\theta\theta}^2 + \cot \theta \partial_\theta + \frac{1}{\sin^2 \theta} \partial_{\phi\phi}^2 \right) Y(\theta, \phi) &= -\ell(\ell+1) Y(\theta, \phi) \end{aligned} \quad (3.8)$$

One might wonder what is the reason for writing the eigenvalue in the form $\ell(\ell+1)$, but as it will turn out soon, there is no loss of generality in this notation.

Separation of the eigenvalue equation

We try the separation of the variables:

$$Y(\theta, \phi) = \Theta(\theta)\Phi(\phi) \quad (3.9)$$

Plugging this into (3.8) and dividing by $\Theta\Phi$, we find

$$\left\{ \frac{1}{\Theta} \left[\sin \theta \frac{d}{d\theta} \left(\sin \theta \frac{d\Theta}{d\theta} \right) \right] + \ell(\ell+1) \sin^2 \theta \right\} + \frac{1}{\Phi} \frac{d^2 \Phi}{d\phi^2} = 0 \quad (3.10)$$

The first term depends only on θ while the last one is a function of only ϕ . In order to satisfy this equation for all values of θ and ϕ these terms must be separately equal to a constant with opposite signs. This constant is traditionally denoted by m^2 and $-m^2$ (note that this is not the mass) and we have two equations: one for Θ , and another for Φ . We consider the second one, and have:

$$\frac{1}{\Phi} \frac{d^2 \Phi}{d\phi^2} = -m^2 \quad (3.11)$$

Two linearly independent solutions are

$$\Phi(\phi) = \begin{cases} e^{im\phi} \\ e^{-im\phi} \end{cases} \quad (3.12)$$

and any linear combinations of them. One can choose $e^{im\phi}$, and include the other one by allowing m to be negative. As these are functions of points in real three dimensional space, the values of $\Phi(\phi)$ and $\Phi(\phi + 2\pi)$ must be the same, as these values of the argument correspond to identical points in space. Then $e^{im(\phi+2\pi)} = e^{im\phi}$, and $e^{im2\pi} = 1$ must hold. From this it follows that m must be an integer

$$\Phi(\phi) = \frac{1}{\sqrt{2\pi}} e^{im\phi} \quad m = 0, \pm 1, \pm 2 \dots \quad (3.15)$$

The integration constant $\frac{1}{\sqrt{2\pi}}$ has been chosen here so that already $\Phi(\phi)$ is normalized to unity when integrating with respect to ϕ from 0 to 2π .

The equation for Θ

$$\sin \theta \frac{d}{d\theta} \left(\sin \theta \frac{d\Theta}{d\theta} \right) + [\ell(\ell+1) \sin^2 \theta - m^2] \Theta = 0 \quad (3.16)$$

is more complicated. With $\cos \theta = z$ the solution is

$$P_\ell^m(z) := (1-z^2)^{|m|/2} \left(\frac{d}{dz} \right)^{|m|} P_\ell(z) \quad (3.17)$$

where $P_\ell(z)$ is the ℓ -th **Legendre polynomial**, defined by the following formula, (called the **Rodriguez formula**):

$$P_\ell(z) := \frac{1}{2^\ell \ell!} \left(\frac{d}{dz} \right)^\ell (z^2 - 1)^\ell \quad (3.18)$$

The functions $P_\ell^m(z)$ are called associated Legendre functions.

Spherical Acceleration Momentum
BASIC REASONING FOR PRINCIPLES & EQUATIONS

LEGENDRE POLYNOMIALS

Legendre Polynomials are a family of orthogonal polynomials that solve the Legendre differential equation and are widely used in mathematical physics and numerical analysis.

Definition and Differential Equation

Legendre polynomials, denoted $P_n(x)$, are solutions to the Legendre differential equation:
$$(1-x^2)d^2P_n/dx^2 - 2xdP_n/dx + n(n+1)P_n(x) = 0$$
where n is a non-negative integer.

These polynomials are named after the French mathematician Adrien-Marie Legendre and are defined over the interval $[-1, 1]$ with orthogonality under the weight function 1 (uniform weight)

Orthogonality

Legendre polynomials satisfy the orthogonality relation:
$$\int_{-1}^1 P_m(x)P_n(x)dx = 0 \text{ for } m \neq n$$

This property makes them useful for expanding functions in Fourier-Legendre series, similar to Fourier series but for functions defined on $[-1, 1]$

Rodrigues' Formula

A convenient formula to generate Legendre polynomials is Rodrigues' formula:
$$P_n(x) = \frac{1}{2^n n!} \frac{d^n}{dx^n} (x^2 - 1)^n$$

This allows explicit computation of $P_n(x)$ for any integer n [Wolfram](https://www.wolfram.com).

Read further at ; <https://phys.libretexts.org/>

LEGENDRE POLYNOMIALS

Definition and Differential Equation

Recurrence Relation

Legendre polynomials satisfy a three-term recurrence relation:

$$(n+1)P_{n+1}(x) = (2n+1)xP_n(x) - nP_{n-1}(x)$$

This relation is useful for computational purposes and for deriving properties of higher-order polynomials Wolfram.

Applications

1. **Physics:** They appear in solutions to Laplace's equation in spherical coordinates, particularly for problems with axial symmetry, such as gravitational and electrostatic potentials
2. **Quantum Mechanics:** Used in solving the Schrödinger equation for central potentials.
3. **Numerical Analysis:** Serve as basis functions in Gaussian quadrature for approximating integrals.
4. **Series Expansions:** Functions can be expanded in Legendre series using the orthogonality property

Examples

The first few Legendre polynomials are:

$$P_0(x)=1, P_1(x)=x, P_2(x)=\frac{1}{2}(3x^2-1), P_3(x)=\frac{1}{2}(5x^3-3x)$$

Higher-order polynomials can be generated using Rodrigues' formula or the recurrence relation

Related Concepts

- Associated Legendre polynomials $P_{nm}(x)$ arise when solving problems with azimuthal dependence in spherical coordinates.
- Generating functions and hypergeometric representations provide alternative ways to define and manipulate Legendre polynomials Wolfram.
- Legendre polynomials form a complete orthogonal system, making them fundamental in both theoretical and applied mathematics, particularly in problems with spherical symmetry.

SPHERICAL HARMONICS

Orthonormal Functions in Angularity

Spherical harmonics are special functions defined on the surface of a sphere that form an orthonormal basis for representing functions and solving angular parts of Laplace's equation.

Notice that ℓ must be a nonnegative **integer** otherwise the definition (3.18) makes no sense, and in addition if $|\ell| > \ell$, then (3.17) yields zero. Thus for any given ℓ , there are $2\ell + 1$ allowed values of m :

$$m = -\ell, -\ell + 1, \dots, -1, 0, 1, \dots, \ell - 1, \ell, \quad \text{for } \ell = 0, 1, 2, \dots \quad (3.19)$$

Note that equation (3.16) – as all second order differential equations – must have other linearly independent solutions different from $P_\ell^m(z)$ for a given value of ℓ and m . One can show however, that these latter solutions are divergent for $\theta = 0$ and $\theta = \pi$, and therefore they are not describing physical states. The solutions

$$Y_\ell^m(\theta, \phi) = \mathcal{N}_{\ell m} P_\ell^m(\cos\theta) e^{im\phi} \quad (3.20)$$

where the absolute values of the constants $\mathcal{N}_{\ell m}$ ensure the normalization over the unit sphere, are called **spherical harmonics**. There are several different conventions for the phases of $\mathcal{N}_{\ell m}$, so one has to be careful with them.

The $Y_\ell^m(\theta)$ functions are thus the eigenfunctions of $\hat{L}$ corresponding to the eigenvalue $\hbar^2 \ell(\ell + 1)$, and they are also eigenfunctions of $\hat{L}_z = -i\hbar \partial_\phi$, because

$$\hat{L}_z Y_\ell^m(\theta, \phi) = -i\hbar \partial_\phi Y_\ell^m(\theta, \phi) = \hbar m Y_\ell^m(\theta, \phi) \quad (3.21)$$

The quantum number ℓ is called **angular momentum quantum number**, or sometimes for a historical reason as azimuthal quantum number, while m is the **magnetic quantum number**.

Concluding the subsection let us note the following important fact. As none of the components of $\hat{\mathbf{L}}$, and thus nor $\hat{L}^2$ depends on the radial distance r from the origin, then any function of the form $\mathcal{R}(r) Y_\ell^m(\theta, \phi)$ will be the solution of the eigenvalue equation above, because from the point of view of the $\hat{\mathbf{L}}$ the $\mathcal{R}(r)$ function is a constant, and we can freely multiply both sides of (3.8). by $\mathcal{R}(r)$.

SPHERICAL HARMONICS

Angular Portions of Equative Solutions

Definition and Mathematical Form

Spherical harmonics, denoted $Y_{lm}(\theta, \phi)$, are functions of the polar angle θ and azimuthal angle ϕ on a sphere. They arise as the angular portion of solutions to Laplace's equation in spherical coordinates, particularly when azimuthal symmetry is absent [Wikipedia+1](#). Each harmonic is labeled by two integers: the degree $l \geq 0$ and the order m with $-l \leq m \leq l$. They satisfy the spherical harmonic differential equation and are eigenfunctions of the angular momentum operators L^2 and L_z in quantum mechanics, with eigenvalues $l(l+1)\hbar^2$ and $m\hbar$, respectively

The general form is:

$$Y_{lm}(\theta, \phi) = N_{lm} P_{lm}(\cos\theta) e^{im\phi}$$

where P_{lm} are associated Legendre polynomials and N_{lm} is a normalization constant ensuring orthonormality

Properties

- Orthonormality: $\int Y_{lm}(\theta, \phi) Y_{l'm'}^*(\theta, \phi) d\Omega = \delta_{ll'} \delta_{mm'}$, where $d\Omega = \sin\theta d\theta d\phi$
- Completeness: Any well-behaved function on the sphere can be expanded as a sum of spherical harmonics: $f(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^l a_{lm} Y_{lm}(\theta, \phi)$
- Eigenfunctions of angular momentum: They are simultaneous eigenstates of L^2 and L_z , making them fundamental in quantum mechanics for describing orbital angular momentum

Examples

For low degrees $l=0,1,2$, the spherical harmonics are:

- $Y_{00} = \frac{1}{4\pi}$
- $Y_{10} = \frac{3}{4\pi} \cos\theta$
- $Y_{1\pm 1} = \mp \frac{3}{8\pi} \sin\theta e^{\pm i\phi}$
- $Y_{20} = \frac{5}{16\pi} (3\cos^2\theta - 1)$
- $Y_{2\pm 1} = \mp \frac{15}{8\pi} \sin\theta \cos\theta e^{\pm i\phi}$
- $Y_{2\pm 2} = \frac{15}{32\pi} \sin^2\theta e^{\pm 2i\phi}$

Applications

- Quantum mechanics: Describing electron orbitals and angular momentum states.
- Geophysics and planetary science: Modeling gravitational and magnetic fields of planets.
- Computer graphics: Efficiently representing lighting and shading on spherical surfaces.
- Acoustics and signal processing: Expanding functions on spherical domains for analysis.
- Spherical harmonics provide a powerful tool for decomposing complex angular functions into simpler, orthogonal components, analogous to Fourier series for periodic functions on a circle

ANGULAR MOMENTUM

Torques Angularity in Interacted Protons

The treatment of angular momentum is very important to understand the properties of atoms. It is now time to explore these effects in detail, and to see how this leads to the classification of the quantized states of atoms by their angular momentum.

Conservation of Angular Momentum

In the sections that follow, we will consider several different types of angular momentum and the ways in which they are coupled together. Before going into the details, it is useful to stress one very important point related to conservation of angular momentum. In an isolated atom, there are many forces (and hence torques) acting inside the atom. These internal forces cannot change the total angular momentum of the atom, since conservation of angular momentum demands that the angular momentum of the atom as a whole must be constant in the absence of any external torques. The total angular momentum of the atom is normally determined by its electrons. The total electronic angular momentum is written J and is specified by the quantum number J . The principle of conservation of angular momentum therefore requires that isolated atoms always have well-defined J -states. It is this J -value that determines, for example, the magnetic dipole moment of the atom.

It should be noted in passing that the nucleus can possess angular momentum and that electrons can exchange angular momentum with the nucleus through hyperfine interactions. These interactions are very weak, and can usually be neglected except when explicitly considering nuclear effects. With this caveat, we can safely regard the total electronic angular momentum J as a conserved quantity.

The principle of conservation of angular momentum does not apply, of course, when external perturbations are applied. The most obvious example is the perturbation caused by the emission or absorption of a photon. In this case the angular momentum of the atom must change because the photon itself carries angular momentum, and the angular momentum of the whole system (atom + photon) has to be conserved. The change in J is then governed by selection rules, such as the effect of a strong external DC magnetic field.

ANGULAR MOMENTUM

Dynamics Quantity

The Dynamical Quantity We Have Ignored

We have spent all of our time in the quantum theory dealing with the three physical quantities of position, momentum, and energy, but there is one other that we studied at length in classical mechanics that has barely been mentioned so far – angular momentum. This is quite an omission, given that it, along with linear momentum and energy, satisfies a very useful conservation principle under the proper conditions. This apparent oversight is even more striking given that Planck's constant, the most fundamental of all physical constants in the realm of quantum mechanics, has units of angular momentum! But avoidance of angular momentum was not an oversight, it just took a lot of background to be able to handle it, and the time is now finally right.

Digression: Types of Vectors

Since Physics 9HA, we have treated angular momentum as though it is a vector. After all, it does have magnitude and direction, right? Well, yes on the magnitude, but we actually defined its direction ourselves with the right-hand-rule – if the majority of humanity had been left-handed, we might have defined its direction as exactly the opposite. It doesn't have a "natural" direction like velocity and momentum does. In fact, angular momentum is an example of a mathematical quantity known as an **axial vector**, or a **pseudovector** ("regular" vectors like momentum and velocity are referred to as **polar vectors**). What distinguishes axial vectors from polar vectors mathematically is how they transform when the coordinate system defining their components is reflected about the origin ($x \rightarrow -x$, $y \rightarrow -y$, $z \rightarrow -z$). Clearly polar vectors will change sign under such a transformation (all of their components flip sign), but see what happens to angular momentum:

$$\left. \begin{array}{l} x \rightarrow -x \\ y \rightarrow -y \\ z \rightarrow -z \end{array} \right\} \rightarrow \vec{L} = \vec{r} \times \vec{p} = (-\vec{r}) \times (-\vec{p}) = +\vec{L} \quad (9.4.1)$$

A Few Brief Words About the Hydrogen Atom

Clearly the radial symmetry of the potential energy of the electron in a hydrogen atom qualifies it for this analysis, but we will not be delving into the details of the eigenfunctions for this system in this class (rest assured it will be a high priority for a future class in quantum physics!). However, there are some interesting/important facts about the hydrogen atom that are worth sharing.

The electron in a hydrogen atom comes with the three quantum numbers already mentioned: n , l , and m_l . From our study of one-dimensional wells, we are used to having a quantum number related directly to energy eigenvalues. In this case, the energy eigenvalue appears imbedded in the radial wave equation, the eigenfunction of which depends on both n and l . It's not surprising that the magnetic quantum number doesn't effect the energy of the electron, since m_l relates to the quantized z -component of angular momentum, and this depends upon our choice of z axis – the energy levels should not depend upon our choice of a z -axis. But certainly it makes sense that the energy of the electron in the Coulomb potential should depend upon the other two. Strangely, however, it does not! It *only* depends upon the principal quantum number, n . Indeed, Bohr's remarkable result of the energy spectrum of hydrogen with his simple model holds up, even when incorporating the angular momentum properly.

The mathematics (which we didn't cover in detail) of the two angular-momentum quantum numbers gave us a restriction on the possible values of m_l for a given value of l (Equation 9.3.15), and it turns out that still more mathematics (that we also won't cover) results in a restriction on the number of l values for a given n . The values of l are restricted to be only positive, and it turns out that they can never exceed the principle quantum number:

$$l = 0, 1, 2, \dots, n-1 \quad (9.4.15)$$

When we first started with 3-dimensions, we noted that the extra degrees of freedom can, especially in cases involving symmetry, lead to degeneracies – multiple wave functions responsible for the same particle energy. Clearly this happens for the hydrogen atom. We already know about the $2l+1$ states that have the same l quantum number but different m_l quantum numbers, and now we see that there are multiple orbital quantum numbers for a given principle quantum number. The degeneracy associated with the multiple values of m_l are attributable to the spherical symmetry, but the degeneracy associated with the l -values is a famous example of an accidental degeneracy (recall these are degeneracies that come from coincidence, and not some symmetry (at least not an obvious one)).

The degeneracy we get for a given principle quantum number can be counted. There are n possible values of l , and for each of these, there are $2l+1$ values of m_l . This leads to the following number of states for the same energy:

$$\begin{aligned} & \text{degeneracy of } n^{\text{th}} \text{ energy eigenstate} \\ & = [1 \ (l=0, m=0)] + [3 \ (l=1, m=0, \pm 1)] + \dots + [2l+1 \ (l=n-1, m=0, \pm 1, \dots, \pm l)] = n^2 \end{aligned} \quad (9.4.16)$$

ANGULAR MOMENTUM

Dynamics Quantity

Read further at ; <https://phys.libretexts.org/>

Building an Angular Momentum Operator

We know from the very origins of our work in quantum mechanics that all physically-observable quantities have quantum-mechanical operators associated with them. We also determined that the operators we needed could be built from a couple of fundamental ones. For example, we built the kinetic energy operator from the momentum operators for each of the three directions:

$$\widehat{KE} = \frac{1}{2m} (\hat{p}_x^2 + \hat{p}_y^2 + \hat{p}_z^2) = -\frac{\hbar^2}{2m} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \quad (9.4.2)$$

Well, classically we can express the components of angular momentum in terms of components of position and momentum, so we should be able to do a similar construction from their operators. We have to use some care, however, because whenever we "mix" position and momentum, the uncertainty principle shows up. Let's start with the classical definition:

$$\vec{L} = \vec{r} \times \vec{p} = (x \hat{i} + y \hat{j} + z \hat{k}) \times (p_x \hat{i} + p_y \hat{j} + p_z \hat{k}) = (yp_z - zp_y) \hat{i} + (zp_x - xp_z) \hat{j} + (xp_y - yp_x) \hat{k} \quad (9.4.3)$$

Let's focus only on the z -component. If we want to create an operator for L_z , we must replace the classical values with operators:

$$\hat{L}_z = \hat{x} \hat{p}_y - \hat{y} \hat{p}_x = -i\hbar \left(x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \quad (9.4.4)$$

The operators for L_x and L_y come out similarly. Speaking of the operators of the other components of angular momentum, close examination of these reveals a brand-new property that we haven't seen before. back in Section 5.3, we found that the uncertainty principle for two "incompatible" physical quantities is manifested in their operators in that they do not produce the same result when they act on a wave function in different orders. Put another way, physical quantities that cannot simultaneously be measured with arbitrary precision have operators that don't commute with each other. We know that the operators representing the components of the position all commute with each other – we can simultaneously measure the x -position, the y -position, and the z -position without the uncertainty principle making them trip over each other. We can similarly do this with the components of linear momentum, since the order of partial derivatives can be freely swapped. But this is not true of the operators of the components of the angular momentum vector! Let's demonstrate this with the x and y components:

$$\begin{aligned} \hat{L}_x \hat{L}_y \Psi &= [-i\hbar(y \frac{\partial}{\partial z} - z \frac{\partial}{\partial y})] [-i\hbar(x \frac{\partial}{\partial z} - z \frac{\partial}{\partial x})] \Psi = -\hbar^2 [y \frac{\partial^2}{\partial z^2} \Psi + yz \frac{\partial^2}{\partial z \partial x} \Psi + xz \frac{\partial^2}{\partial y \partial z} \Psi - x^2 \frac{\partial^2}{\partial x \partial y} \Psi - xy \frac{\partial^2}{\partial x^2} \Psi] \\ \hat{L}_y \hat{L}_x \Psi &= [-i\hbar(x \frac{\partial}{\partial z} - z \frac{\partial}{\partial x})] [-i\hbar(y \frac{\partial}{\partial z} - z \frac{\partial}{\partial y})] \Psi = -\hbar^2 [x \frac{\partial^2}{\partial z^2} \Psi + yz \frac{\partial^2}{\partial z \partial x} \Psi + xz \frac{\partial^2}{\partial y \partial z} \Psi - x^2 \frac{\partial^2}{\partial x \partial y} \Psi - xy \frac{\partial^2}{\partial y^2} \Psi] \end{aligned} \quad (9.4.5)$$

We see that the derivatives of the second (leftmost) operator act on the position components present in the second (rightmost) operator. The derivatives make quite a mess in each case, but the point is that the two "messes" are not equal, as can be seen by comparing the two results above – the last 4 terms are all the same, but the first terms differ. If one measures the x -component of angular momentum of a particle precisely, knowledge of the y component of the same angular momentum vector is lost!

Another extremely interesting (and as it happens, useful!) result we get from above is that we can construct an operator of one component of the angular momentum from the other two. Start by subtracting the two results above. This gets rid of the last four common terms and leaves:

$$(\hat{L}_x \hat{L}_y - \hat{L}_y \hat{L}_x) \Psi = \hbar^2 \left(x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \Psi \quad (9.4.6)$$

The right side of this equation looks familiar – it is very nearly the operator of the z -component of angular momentum (Equation 9.4.4). Indeed we have:

$$\hat{L}_x \hat{L}_y - \hat{L}_y \hat{L}_x = i\hbar \hat{L}_z \quad (9.4.7)$$

There is a shorthand notation frequently used in such situations, called the **commutator** of the operators $\hat{A}$ and $\hat{B}$:

$$[\hat{A}, \hat{B}] \equiv \hat{A}\hat{B} - \hat{B}\hat{A} \quad (9.4.8)$$

Thanks to the cyclical nature of the cross-product, we can similarly construct all the components from the other two, so we have:

$$[\hat{L}_x, \hat{L}_y] = i\hbar \hat{L}_z, \quad [\hat{L}_y, \hat{L}_z] = i\hbar \hat{L}_x, \quad [\hat{L}_z, \hat{L}_x] = i\hbar \hat{L}_y \quad (9.4.9)$$

These are known as the **commutation relations** of the angular momentum component operators.

ANGULAR MOMENTUM

Magnitude Equations

Magnitude of Angular Momentum

We now know how the components of angular momentum relate to each other, but what can be said about the *magnitude* of the angular momentum (or its magnitude-squared, which is more commonly used)? Interestingly, this measurable quantity commutes with all of the components:

$$[\bar{L}^2, \bar{L}_x] = [\bar{L}^2, \bar{L}_y] = [\bar{L}^2, \bar{L}_z] = 0 \quad \bar{L}^2 = \bar{L}_x^2 + \bar{L}_y^2 + \bar{L}_z^2 \quad (9.4.10)$$

We will not do so here, but this fact can be proven using purely the commutation relations between the components. The physical meaning is that a particle can be in an eigenstate of total momentum, and one of its components can simultaneously be known to arbitrary precision. But because of the uncertainty relation between the components, the particle can be in an eigenstate of *only one* of those components at a time. We can depict this in a diagram as follows. Let's suppose that we measure both the total magnitude of angular momentum and the z -component precisely, then the uncertain vector angular momentum state of the particle looks like the figure below.

Figure 9.4.1 – Uncertain Angular Momentum Vector

Uncertainty in the vector $\vec{L}$ is characterized by the circle shown around the z -axis – every such vector with a tail at the origin and the head landing in the edge of that circle is possible. Note that the *length* of the angular momentum vector is known precisely, as is the z -component, but the x and y components are unknown.

ANGULAR MOMENTUM

Spherical Coordinates Equations

Read further at ; <https://phys.libretexts.org/>

Using Spherical Coordinates

In defining spherical coordinates, we have selected-out the z -direction as special (it is the axis from which the polar angle is measured, and around which the azimuthal angle is measured). By convention, we therefore define that to be the direction for which the single component of angular momentum is known. We can convert the operator $\hat{L}_z$ into spherical coordinates to get an operator to use in cases where spherical coordinates are in play. The amount of math busywork requires to show this is substantial, but the end result is remarkably simple:

$$\hat{L}_z = -i\hbar \frac{\partial}{\partial \phi} \quad (9.4.11)$$

If the potential acting on a particle happens to be spherically symmetric, then the separated stationary-state wave function has an azimuthal piece given by Equation 7.3.12, and it's clear that this is an eigenfunction of the z -component of angular momentum:

$$\hat{L}_z \Psi_{nlm_l}(r, \theta, \phi) = -i\hbar \frac{\partial}{\partial \phi} [R_{nl}(r) \Theta_{lm_l}(\theta) e^{im_l \phi}] = m_l \hbar \Psi_{nlm_l}(r, \theta, \phi) \quad (9.4.12)$$

The quantum number m_l therefore describes the quantized z component of angular momentum – the eigenvalue is this integer multiplied by $\hbar$.

The operator use in spherical coordinates for $\hat{L}^2$ is considerably more complicated than the one for $\hat{L}_z$, and we will not take the discussion this deep in this class. But it is important to know that the polar portion of the separated wave function (the Legendre polynomials, $\Theta_{lm_l}(\theta)$), for which we have also postponed examination to a future, more advanced class) are eigenfunctions of this operator. Specifically:

$$\hat{L}^2 \Psi_{nlm_l}(r, \theta, \phi) = \hat{L}^2 [R_{nl}(r) \Theta_{lm_l}(\theta) e^{im_l \phi}] = l(l+1) \hbar^2 \Psi_{nlm_l}(r, \theta, \phi) \quad (9.4.13)$$

The quantum number l therefore describes the quantized magnitude-squared of angular momentum – the eigenvalue is $l(l+1)$ multiplied by $\hbar^2$. Or, if you like, the eigenvalue for the magnitude of angular momentum is $|\vec{L}| = \sqrt{l(l+1)}\hbar$.

To see further justification for this eigenvalue for the square of the total angular momentum, take a look at the radial Schrödinger equation (Equation 9.3.16). The terms on the left side of the equation that do not include the potential energy must be the kinetic energy (since the right hand side is the total energy). The kinetic energy can be divided into a part that comes from radial motion and a part that comes from tangential motion. We did a similar thing in Physics 9HA when discussing gravitation, and wrote the tangential part of the kinetic energy in terms of the angular momentum in Equation 9.3.8. Comparing these immediately suggests that $L^2 = l(l+1)\hbar^2$.

Given that the z -component of the angular momentum must always be strictly less than the magnitude of the angular momentum vector (the x and y components can never be zero due to uncertainty), the relation given in Equation 9.3.15, limiting the value of m_l to extremes of $\pm l$, and this magnitude of $\vec{L}$ are perfectly consistent. This leads to the number of possible quantized angular momentum states for a given quantum number l to be:

$$\text{number of quantized angular momentum states} = 2l + 1 \quad (9.4.14)$$

For example, for $l = 1$:

Figure 9.4.2 – Quantized Angular Momentum States ($l = 1$)

SPHERICAL COORDINATE

Cartesian Systems

The spherical coordinate system is defined with respect to the Cartesian system in Figure 4.4.1. The spherical system uses r , the distance measured from the origin; θ , the angle measured from the $+z$ axis toward the $z = 0$ plane; and ϕ , the angle measured in a plane of constant z , identical to ϕ in the cylindrical system.

Figure 4.4.1: Spherical coordinate system and associated basis vectors. (CC BY SA 4.0; K. Kikkeri).

Spherical coordinates are preferred over Cartesian and cylindrical coordinates when the geometry of the problem exhibits spherical symmetry. For example, in the Cartesian coordinate system, the surface of a sphere concentric with the origin requires all three coordinates (x , y , and z) to describe. However, this surface can be described using a single constant parameter – the radius r – in the spherical coordinate system. This leads to a dramatic simplification in the mathematics in certain applications.

The basis vectors in the spherical system are $\hat{r}$, $\hat{\theta}$, and $\hat{\phi}$. As always, the dot product of like basis vectors is equal to one, and the dot product of unlike basis vectors is equal to zero. For the cross-products, we find:

$$\hat{r} \times \hat{\theta} = \hat{\phi}$$

$$\hat{\theta} \times \hat{\phi} = \hat{r}$$

$$\hat{\phi} \times \hat{r} = \hat{\theta}$$

Read further at ; <https://phys.libretexts.org/>

SPHERICAL COORDINATE

Cartesian Systems

Like the cylindrical system, the spherical system is often less useful than the Cartesian system for identifying absolute and relative positions. The reason is the same: Basis directions in the spherical system depend on position. For example, $\hat{r}$ is directed radially outward from the origin, so $\hat{r} = \hat{x}$ for locations along the x -axis but $\hat{r} = \hat{y}$ for locations along the y axis and $\hat{r} = \hat{z}$ for locations along the z axis. Similarly, the directions of $\hat{\theta}$ and $\hat{\phi}$ vary as a function of position. To overcome this awkwardness, it is common to begin a problem in spherical coordinates, and then to convert to Cartesian coordinates at some later point in the analysis. Here are the conversions:

$$x = r \cos \phi \sin \theta \quad (4.4.1)$$

$$y = r \sin \phi \sin \theta \quad (4.4.2)$$

$$z = r \cos \theta \quad (4.4.3)$$

The conversion from Cartesian to spherical coordinates is as follows:

$$r = \sqrt{x^2 + y^2 + z^2} \quad (4.4.4)$$

$$\theta = \arccos(z/r) \quad (4.4.5)$$

$$\phi = \arctan(y, x) \quad (4.4.6)$$

where $\arctan$ is the four-quadrant [inverse tangent function](#).

K. Kikkeri).

Figure 4.4.2 Cross products among basis vectors in the spherical system. (See Figure 4.1.10 for instructions on the use of this diagram.) (CC BY SA 4.0;

Dot products between basis vectors in the spherical and Cartesian systems are summarized in Table 4.4.1. This information can be used to convert between basis vectors in the spherical and Cartesian systems, in the same manner described in Section 4.3; e.g.

$$\hat{x} = \hat{r} (\hat{r} \cdot \hat{x}) + \hat{\theta} (\hat{\theta} \cdot \hat{x}) + \hat{\phi} (\hat{\phi} \cdot \hat{x})$$

$$\hat{r} = \hat{x} (\hat{x} \cdot \hat{r}) + \hat{y} (\hat{y} \cdot \hat{r}) + \hat{z} (\hat{z} \cdot \hat{r})$$

Table 4.4.1: Dot products between basis vectors in the spherical and Cartesian coordinate systems.

	$\hat{r}$	$\hat{\theta}$	$\hat{\phi}$
$\hat{x}$	$\sin \theta \cos \phi$	$\cos \theta \cos \phi$	$-\sin \phi$
$\hat{y}$	$\sin \theta \sin \phi$	$\cos \theta \sin \phi$	$\cos \phi$
$\hat{z}$	$\cos \theta$	$-\sin \theta$	0

✓ Example 4.4.1: Cartesian to spherical conversion

A vector field $G = \hat{x} \, xz/y$. Develop an expression for G in spherical coordinates.

Solution

Simply substitute expressions in terms of spherical coordinates for expressions in terms of Cartesian coordinates. Use Table 4.4.1 and Equations 4.4.1- 4.4.3. Making these substitutions and applying a bit of mathematical clean-up afterward, one obtains

$$G = (\hat{r} \sin \theta \cot \phi + \hat{\phi} \cos \theta \cot \phi - \hat{\phi}) \cdot r \cos \theta \cos \phi$$

SPHERICAL COORDINATE

Cartesian Systems

Read further at ; <https://phys.libretexts.org/>

Integration Over Length

A differential-length segment of a curve in the spherical system is

$$d\mathbf{l} = \hat{r} dr + \hat{\theta} r d\theta + \hat{\phi} r \sin \theta d\phi$$

Note that θ is an angle, as opposed to a distance. The associated distance is $r d\theta$ in the θ direction. Note also that in the ϕ direction, distance is $r d\phi$ in the $z = 0$ plane and less by the factor $\sin \theta$ for $z \neq 0$.

As always, the integral of a vector field $\mathbf{A}(\mathbf{r})$ over a curve $\mathcal{C}$ is

$$\int_{\mathcal{C}} \mathbf{A} \cdot d\mathbf{l}$$

To demonstrate line integration in the spherical system, imagine a sphere of radius a centered at the origin with "poles" at $z = +a$ and $z = -a$. Let us calculate the integral of $\mathbf{A}(\mathbf{r}) = \hat{\theta}$, where $\mathcal{C}$ is the arc drawn directly from pole to pole along the surface of the sphere, as shown in Figure 4.4.3. In this example, $d\mathbf{l} = \hat{\theta} a d\theta$ since $r = a$ and ϕ (which could be any value) are both constant along $\mathcal{C}$. Subsequently, $\mathbf{A} \cdot d\mathbf{l} = a d\theta$ and the above integral is

$$\int_0^\pi a d\theta = \pi a$$

i.e., half the circumference of the sphere, as expected.

Figure 4.4.3: Example in spherical coordinates: Pole-to-pole distance on a sphere. (CC BY SA 4.0; K. Kikkeri).]

Note that the spherical system is an appropriate choice for this example because the problem can be expressed with the minimum number of varying coordinates in the spherical system. If we had attempted this problem in the Cartesian system, we would find that both z and either x or y (or all three) vary over $\mathcal{C}$ and in a relatively complex way.

SPHERICAL COORDINATE

Cartesian Systems

Integration Over Area

Now we ask the question, what is the integral of some vector field $\mathbf{A}$ over the surface $\mathcal{S}$ of a sphere of radius a centered on the origin? This is shown in Figure 4.4.4. The differential surface vector in this case is

$$d\mathbf{s} = \hat{\mathbf{r}} (r d\theta) (r \sin \theta d\phi) = \hat{\mathbf{r}} r^2 \sin \theta d\theta d\phi$$

Figure 4.4.4: Example in spherical coordinates: The area of a sphere. (CC BY SA 4.0; K. Kikkeri).

As always, the direction is normal to the surface and in the direction associated with positive flux. The quantities in parentheses are the distances associated with varying θ and ϕ , respectively. In general, the integral over a surface is

$$\int_{\mathcal{S}} \mathbf{A} \cdot d\mathbf{s}$$

In this case, let's consider $\mathbf{A} = \hat{\mathbf{r}}$; in this case $\mathbf{A} \cdot d\mathbf{s} = a^2 \sin \theta d\theta d\phi$ and the integral becomes

$$\begin{aligned} \int_0^\pi \int_0^{2\pi} a^2 \sin \theta d\theta d\phi &= a^2 \left(\int_0^\pi \sin \theta d\theta \right) \left(\int_0^{2\pi} d\phi \right) \\ &= a^2 (2) (2\pi) \\ &= 4\pi a^2 \end{aligned}$$

which we recognize as the area of the sphere, as expected. The corresponding calculation in the Cartesian or cylindrical systems is quite difficult in comparison.

Read further at ; <https://phys.libretexts.org/>

SPHERICAL COORDINATE

Cartesian Systems

Integration Over Volume

The differential volume element in the spherical system is

$$dv = dr (r d\theta) (r \sin \theta d\phi) = r^2 dr \sin \theta d\theta d\phi$$

For example, if $A(r) = 1$ and the volume $\mathcal{V}$ is a sphere of radius a centered on the origin, then

$$\begin{aligned}\int_{\mathcal{V}} A(r) dv &= \int_0^a \int_0^\pi \int_0^{2\pi} r^2 dr \sin \theta d\theta d\phi \\ &= \left(\int_0^a r^2 dr \right) \left(\int_0^\pi \sin \theta d\theta \right) \left(\int_0^{2\pi} d\phi \right) \\ &= \left(\frac{1}{3} a^3 \right) (2) (2\pi) \\ &= \frac{4}{3} \pi a^3\end{aligned}$$

which is the volume of a sphere.

QUARK ATOMIC SCALE FLUX

quantum sensor vibratic measurements

In short, atomic-scale flux vibrations are measured with quantum sensors in STM setups, while hadron-scale flux is probed through accelerator magnetic systems and hadron yield fluctuations in collisions.

- Flux in physics usually refers to something flowing through a surface — like electric field lines, magnetic field lines, or particle currents.
- Quarks, however, are confined inside hadrons (protons, neutrons, mesons) due to quantum chromodynamics (QCD). They don't flow freely in the same sense as electrons or photons, because of confinement.
- What is meaningful is the concept of color flux tubes: in QCD, the strong force between quarks is often modeled as a flux tube of gluon fields connecting them. This is why quarks are bound together — the “flux” of the color field doesn't spread out like electromagnetism, it stays confined.
- In lattice QCD simulations, physicists actually visualize these color flux tubes to study how quarks interact and how hadrons form.
- the counting of the wavelength of the flux in the quark scale. it is rotating flux
- one of the most subtle aspects of quantum chromodynamics (QCD) at the quark scale, the “flux” we talk about is the color flux tube — the gluon field that binds quarks together. It's not a free-flowing wave like light, but rather a confined tube of energy. Still, physicists sometimes describe its excitations in terms of wavelengths or modes, similar to vibrations on a string.

QUARK ATOMIC SCALE FLUX

quantum sensor vibratic measurements

In short, atomic-scale flux vibrations are measured with quantum sensors in STM setups, while hadron-scale flux is probed through accelerator magnetic systems and hadron yield fluctuations in collisions.

Wavelength of Quark Flux

- In lattice QCD simulations, the flux tube between quarks can support vibrational modes. These modes have effective “wavelengths” determined by the separation of the quarks and the energy density of the gluon field.
- The lowest mode corresponds to the linear confinement potential (like a stretched string). Higher modes resemble standing waves along the flux tube.
- Unlike photons or electrons, these “wavelengths” aren’t directly measurable in free space — they’re inferred from hadron spectra and lattice calculations.

Rotating Flux?

- Yes, in a sense: when quarks form bound states with angular momentum (like mesons with spin), the flux tube can rotate.
- This rotation manifests as Regge trajectories — a linear relationship between the squared mass of a hadron and its angular momentum. That’s essentially the “rotating flux tube” picture.
- So when you say “rotating flux,” you’re describing the rotational excitations of the color flux tube that give rise to families of hadrons with increasing spin.

Putting It Together

- Counting wavelengths → corresponds to identifying vibrational modes of the flux tube.
- Rotating flux → corresponds to angular momentum excitations, seen in hadron spectra.
- Both are ways of modeling confinement and explaining why quarks never exist freely but always as part of hadrons.

Mathematical Continuity Model of Quark Flux

Flux Conservation from Quarks to Molecules

Quark Scale. Quark Flux Dynamics

$$\partial_{\mu} J^{\mu}_{total} = 0$$

$$J^{\mu}_{total} = a_{QCD} J^{\mu}_{QCD} + a_{QED} J^{\mu}_{QED} + a_{Weak} J^{\mu}_{Weak} + a_{Gravity}$$

Hadron Scale. Confinement Integration

$$M_H = \int_{V_L} \bar{F}_{lux}(z) d^3r$$

$$\bar{\mu}_H = \int_{V_H} \bar{H}_r r \times J^{\mu}_{QED} d^3r$$

Atomic Scale. Electromagnetic Continuity

$$\nabla \cdot E = \hat{p}_{(QED)}$$

$$\nabla \times 0 = \mu_0 \hat{J}_{QED} + \mu_0 0 \frac{\partial E}{\partial t}$$

Molecular Scale. Chemical Bond Flux

$$\nabla \cdot J_{molecular} = - \frac{\mathcal{L}p}{e_{bond}} / \delta t$$

Unified Continuity Condition

$$\partial_{\mu} J^{\mu}_{-quark} \rightarrow \partial_{\mu} J^{\mu}_{-hadron} \rightarrow \partial_{\mu} J^{\mu}_{-atomic} \rightarrow \partial_{\mu} J^{\mu}_{-molecular} = 0$$

QUARK FLUX

unified concepts at hadron scales

not all particles are “color-charged.” In fact, many fundamental particles — like electrons, photons, neutrinos — don’t carry color charge at all. That’s why physicists don’t describe their interactions in terms of color flux.

Here’s the distinction:

✚ Color-Charged vs Non-Color Particles

- Quarks & Gluons → These do carry color charge, so their interactions are governed by QCD. The “flux” we talk about here is the color flux tube that confines quarks inside hadrons.
- Electrons, Photons, Neutrinos, etc. → These are non-color particles. Their interactions are described by QED (electromagnetism) or the weak force, not QCD. For them, we talk about electric flux or magnetic flux, not color flux.
- Color flux tubes in QCD → the gluon fields that confine quarks inside hadrons.
- Flux tube excitations → vibrational and rotational modes of those tubes, which explain hadron spectra and Regge trajectories.
- Lattice QCD simulations → numerical studies that visualize and measure the energy density of these flux tubes between quarks.

Quark Flux is more inclusive term that doesn’t lock the discussion into just QCD’s “color flux.” From that perspective, “quark flux” could serve as a conceptual umbrella: it would cover not only the color-charged gluon interactions but also the way quarks couple indirectly to non-color fields (like electromagnetic interactions, weak currents, or even vibrational counting at the hadron scale).

- “Flux” in physics usually refers to field lines or currents through a surface. Since quarks themselves are confined, researchers describe the fields (gluons) rather than the quarks as flux carriers.
- Non-color particles (like electrons or neutrinos) don’t interact via QCD, so they’re studied under different flux concepts (electric, magnetic, weak).
- If you want to count vibrational modes or wavelengths at the hadron scale, it’s natural to think of all contributions — color flux, electromagnetic flux, and even weak flux — as part of a bigger “quark flux” picture.
- This would emphasize the total flux environment around quarks, not just the color confinement piece.

QUARK FLUX FRAMEWORK

unified concepts at hadron scales

1. Color Flux (QCD)

- **Origin:** Gluon fields between quarks.
- **Behavior:** Forms confined flux tubes, vibrational and rotational modes.
- **Observable:** Hadron spectra, Regge trajectories, confinement potential.

2. Electromagnetic Flux (QED)

- **Origin:** Quarks carry electric charge (e.g., up quark $+2/3$, down quark $-1/3$).
- **Behavior:** Produces electric/magnetic flux around hadrons.
- **Observable:** Magnetic moments of protons/neutrons, scattering cross-sections.

3. Weak Flux (Electroweak)

- **Origin:** Quarks interact via W and Z bosons.
- **Behavior:** Short-range flux, contributes to flavor-changing processes.
- **Observable:** Beta decay, neutrino scattering.

4. Gravitational Flux (Speculative at Quark Scale)

- **Origin:** Energy density of quark-gluon fields.
- **Behavior:** Extremely weak compared to QCD/QED, but conceptually part of the flux environment.
- **Observable:** Not measurable directly at quark scale, but relevant in cosmology (early universe, neutron stars).

Flux Type	Carrier Field	Role at Quark Scale	Observable Effect
Color Flux	Gluons	Confinement, vibrations	Hadron mass spectrum
EM Flux	Photons	Charge interactions	Magnetic moments, scattering
Weak Flux	W/Z bosons	Flavor change, decay	Beta decay, neutrino events
Gravitational Flux	Spacetime curvature	Energy coupling	Cosmological models

QUARK FLUX FRAMEWORK

unified concepts at hadron scales

🌟 Why “Quark Flux” Works

By calling it **quark flux**, you’re emphasizing the *total flux environment* around quarks — not just the color confinement piece. It’s a broader, more intuitive term that includes:

- Vibrational counting (color flux tubes).
- Rotational excitations (Regge trajectories).
- Electromagnetic and weak contributions.
- Even speculative gravitational coupling.

👉 In other words, “**quark flux**” = **the sum of all flux interactions at the quark scale.**

🧩 The 4D Equation

At the center of the framework is the combined flux current:

$$J_{\text{quark flux}}^{\mu} = J_{\text{QCD}}^{\mu} + J_{\text{QED}}^{\mu} + J_{\text{Weak}}^{\mu} + J_{\text{Gravity}}^{\mu}$$

- $J_{\text{QCD}}^{\mu} = g_s \bar{q} \gamma^{\mu} \lambda^a q \rightarrow$ color flux (gluons, confinement tubes).
- $J_{\text{QED}}^{\mu} = e \bar{q} \gamma^{\mu} q \rightarrow$ electromagnetic flux (photon interactions, magnetic fields).
- $J_{\text{Weak}}^{\mu} = g_W \bar{q} \gamma^{\mu} (1 - \gamma^5) q \rightarrow$ weak flux (W/Z bosons, flavor changes).
- $J_{\text{Gravity}}^{\mu} = \kappa T_v^{\mu} \rightarrow$ gravitational flux (energy density, curvature effects).

Quark Flux Multi-Scale Model

From Quark Dynamics to Atomic and Molecular Scales

QUARK FLUX LOGICS

Prediction Logics at Quark Levels

🔄 Flow of Concepts

- Color Flux (QCD): confinement, vibrational/rotational modes.
- Electromagnetic Flux (QED): charge interactions, magnetic moments.
- Weak Flux: decay processes, neutrino scattering.
- Gravitational Flux: speculative but included for completeness.

All arrows converge into Quark Flux Observables: hadron spectra, decay rates, magnetic moments, and energy density.

This way, “quark flux” becomes a multidimensional construct — not limited to color charge, but inclusive of all flux contributions at the quark scale.

This unified equation could be applied to predict hadron properties (like masses or decay rates) by weighting each flux contribution. The framework are not just conceptual, but computational.

Take the Quark Flux Framework and turn it into a predictive model. This will show how the 4D flux equation can be used to estimate hadron properties like mass, magnetic moment, and decay rate by weighting each flux component.

This model treats quark flux as a multidimensional field — each interaction contributes to the total flux density. By adjusting the coefficients $\alpha_i, \beta_i, \gamma_i$, you can fit experimental data and predict new hadron properties. This predictive flow able to show how each flux component feeds into mass, magnetic moment, and decay rate

5. Flow of Prediction Logic

Step	Input	Process	Output
1	Flux field data (QCD, QED, Weak, Gravity)	Compute weighted flux density	$\rho_{\text{flux}}(r)$
2	Integrate over spatial domain	Calculate total energy	Hadron mass M_H
3	Extract rotational components	Compute magnetic moment	μ_H
4	Evaluate weak flux intensity	Estimate decay rate	Γ_H

QUARK FLUX CONCEPTS

Using Scientific Research at Quark Levels

⚙ Predictive Application of the Quark Flux Equation

1. Start from the 4D Combined Flux Equation

$$J_{\text{quark flux}} = J_{\text{QCD}}\mu + J_{\text{QED}}\mu + J_{\text{Weak}}\mu + J_{\text{Gravity}}\mu$$

Each term contributes differently to observable quantities. To predict hadron properties, we introduce flux weighting coefficients α_i that represent the relative strength of each interaction:

$$J_{\text{total}}\mu = \alpha_{\text{QCD}}J_{\text{QCD}}\mu + \alpha_{\text{QED}}J_{\text{QED}}\mu + \alpha_{\text{Weak}}J_{\text{Weak}}\mu + \alpha_{\text{Gravity}}J_{\text{Gravity}}\mu$$

2. Predicting Hadron Mass

Hadron mass M_H can be modeled as the integrated energy density of the flux fields:

$$M_H = \int \rho_{\text{flux}}(r) d^3r$$

where

$$\rho_{\text{flux}}(r) = \sum_i \alpha_i |J_i\mu(r)|^2$$

This gives a mass prediction based on the combined flux intensity at the quark scale.

3. Predicting Magnetic Moment

Magnetic moment μ_H arises mainly from QED and QCD flux rotation:

$$\mu_H = \beta_{\text{QED}} \mathbf{B}_{\text{QED}} + \beta_{\text{QCD}} \mathbf{B}_{\text{QCD}}$$

Here, $\mathbf{B}_{\text{QED}}$ and $\mathbf{B}_{\text{QCD}}$ are the magnetic field components of the respective fluxes, and β_i are scaling factors derived from experimental data.

4. Predicting Decay Rate

Weak flux dominates decay processes. The decay rate Γ_H can be expressed as:

$$\Gamma_H = \gamma_{\text{Weak}} |J_{\text{Weak}}\mu|^2 + \gamma_{\text{QCD}} |J_{\text{QCD}}\mu|^2$$

This links the strength of weak and color flux interactions to measurable lifetimes.

Quark Flux Simulation Pipeline

Numerical Workflow to Predict Hadron Properties

How the Prediction Flow Works

Input Flux Components: Each interaction (QCD, QED, Weak, Gravity) is represented by its 4D current J_μ . These are weighted by coefficients α_i to form the total flux current.

Weighted Flux Density: The combined flux density is calculated as

$$\rho_{\text{flux}}(r) = \sum_i \alpha_i |J_\mu(r)|^2$$

This represents the total energy density around quarks.

Property Calculations:

- **Mass:** $M_H = \int \rho_{\text{flux}}(r) d^3r$
- **Magnetic Moment:** $\mu_H = \beta_{\text{QED}} \langle B_{\text{QED}} \rangle + \beta_{\text{QCD}} \langle B_{\text{QCD}} \rangle$
- **Decay Rate:** $\Gamma_H = \gamma_{\text{Weak}} |J_{\text{Weak}}|^2 + \gamma_{\text{QCD}} |J_{\text{QCD}}|^2$

Outputs: The model predicts hadron mass, magnetic moment, and decay rate — all derived from the unified quark flux environment.

This diagram makes the framework computationally actionable: by adjusting the weighting coefficients $\alpha_i, \beta_i, \gamma_i$, you can fit experimental data and simulate new hadron properties.

To structure a numerical simulation outline for the Quark Flux Prediction Model — turning the theoretical framework into a computational workflow suitable for symbolic or lattice-based analysis.

Numerical Simulation Outline

1. Define the Flux Components

Each flux current is represented as a 4D tensor field:

$$J_\mu(x) = \text{interaction strength} \times \text{field operator}$$

To define:

- $J_{\text{QCD}}^\mu = g_s q^\dagger \gamma^\mu \lambda a q$
- $J_{\text{QED}}^\mu = e q^\dagger \gamma^\mu q$
- $J_{\text{Weak}}^\mu = g_W q^\dagger \gamma^\mu (1 - \gamma_5) q$
- $J_{\text{Gravity}}^\mu = \kappa T^\mu_\nu$

These can be encoded as symbolic functions or lattice operators.

QUARK FLUX PREDICTIONS FLOW

Flux Components & Lattice Functions

QUARK FLUX LATTICES

component equations flow predictions

2. Initialize Simulation Parameters

Parameter	Description	Typical Range
g_s, e, g_W, κ	Coupling constants	Experimentally known
$\alpha_i, \beta_i, \gamma_i$	Weighting coefficients	Tuned via data fitting
Lattice size	Spatial resolution	$32^3 \times 64$ typical
Temperature	For thermal QCD simulations	100–500 MeV

- **Compute Weighted Flux Density**
 For each lattice point x :

$$\rho_{\text{flux}}(x) = \sum_i \alpha_i |J_i \mu(x)|^2$$

 This step integrates all flux contributions numerically.
- **Integrate for Hadron Mass**
 Use numerical integration over the lattice:

$$M_H = \sum x \rho_{\text{flux}}(x) \Delta V$$

 where ΔV is the lattice cell volume.
- **Extract Magnetic Moment**
 Compute rotational components of QED and QCD flux:

$$\mu_H = \beta_{\text{QED}} \langle B_{\text{QED}} \rangle + \beta_{\text{QCD}} \langle B_{\text{QCD}} \rangle$$

 Use Fourier transforms to extract field rotations.
- **Estimate Decay Rate**
 Evaluate weak flux intensity:

$$\Gamma_H = \gamma_{\text{Weak}} |J_{\text{Weak}} \mu|^2 + \gamma_{\text{QCD}} |J_{\text{QCD}} \mu|^2$$

 Average over time steps to get decay probability.

- Output and Validation**
 Compare simulated results with experimental data:
- Hadron masses (e.g., proton, neutron, mesons)
 - Magnetic moments
 - Decay lifetimes
- Adjust coefficients $\alpha_i, \beta_i, \gamma_i$ iteratively to minimize error.

- ⚙️ **Computational Flow Summary**
1. Initialize constants and lattice grid
 2. Compute flux tensors for each interaction
 3. Combine into total flux density
 4. Integrate for mass, extract rotation for magnetic moment, evaluate weak flux for decay
 5. Fit results to experimental data

Theorization Steps Overview

Initialize Parameters

- Set coupling constants g_s, e, g_W, κ .
- Input weighting coefficients $\alpha_i, \beta_i, \gamma_i$.
- Configure lattice grid and temperature range.

Compute Flux Components

- Calculate QCD, QED, Weak, and Gravity flux tensors $J_{i\mu}(x)$.
- Store them as 4D arrays for each lattice point.

Calculate Weighted Flux Density

- Combine fluxes:

$$\rho_{\text{flux}}(x) = \sum_i \alpha_i |J_{i\mu}(x)|^2$$

Mass Integration

- Integrate over lattice volume:

$$M_H = \sum x \rho_{\text{flux}}(x) \Delta V$$

Magnetic Moment Extraction

- Compute rotational field components:

$$\mu_H = \beta_{\text{QED}} \langle B_{\text{QED}} \rangle + \beta_{\text{QCD}} \langle B_{\text{QCD}} \rangle$$

Decay Rate Estimation

- Evaluate weak flux intensity:

$$\Gamma_H = \gamma_{\text{Weak}} |J_{\text{Weak}\mu}|^2 + \gamma_{\text{QCD}} |J_{\text{QCD}\mu}|^2$$

Compare & Refine

- Validate against experimental data.
- Iteratively adjust coefficients to minimize error.

This pipeline makes the quark flux model computationally actionable — you can simulate hadron properties by integrating flux densities and refining parameters until the results align with observed data.

Theory Flow Highlights

- **Initialize Parameters**
 - Set coupling constants and lattice configuration.
 - Input weighting coefficients for all flux types.
- **Compute Flux Components**
 - QCD Flux: $gsq^{-1}\gamma\mu\lambda aq$
 - QED Flux: $eq^{-1}\gamma\mu q \leftarrow$ now correctly second in order
 - Weak Flux: $gWq^{-1}\gamma\mu(1-\gamma_5)q$
 - Gravity Flux: $\kappa T\mu\nu$
- **Weighted Flux Density Calculation**
$$\rho_{flux}(x) = \sum_i \alpha_i |J_i\mu(x)|^2$$
- **Mass, Magnetic Moment, and Decay Rate Computations** Each derived from the integrated or rotational properties of the flux density.
- **Compare & Refine** Validate against experimental data and iteratively adjust coefficients.

This corrected version ensures the QED flux is properly positioned, reflecting its physical role as the second major interaction after QCD in the simulation sequence.

Why This Matters

This model shows how quark-level flux interactions propagate upward, influencing everything from hadron stability to atomic spectra and molecular chemistry. It's a conceptual bridge between quantum chromodynamics (QCD) and quantum electrodynamics (QED) — a step toward a unified field description.

Theoretical Framework Overview

- Quark Scale – Quark Flux Dynamics
 - Unified flux equation:

$$J_{\text{total}}\mu = \alpha_{\text{QCD}}J_{\text{QCD}}\mu + \alpha_{\text{QED}}J_{\text{QED}}\mu + \alpha_{\text{Weak}}J_{\text{Weak}}\mu + \alpha_{\text{Gravity}}J_{\text{Gravity}}\mu$$

Outputs: hadron mass, magnetic moment, decay rate.

- Hadron Scale – Property Prediction
 - Derived quantities: M_H, μ_H, Γ_H .
 - These feed into the next scale as effective parameters for atomic modeling.
- Atomic Scale – Structure Modeling
 - Uses hadron properties to compute energy levels and electromagnetic transitions.
 - Links QED flux to electron orbital behavior.
- Molecular Scale – Interaction Modeling
 - Extends atomic flux coupling to chemical bonding and reaction rates.
 - Integrates weak and electromagnetic flux effects for complex systems.
- Unified Framework
 - Bridges all scales through flux continuity — the same underlying field principles apply from quarks to molecules.
 - Enables cross-scale simulations and experimental validation.

quark-level flux dynamics

MULTI-SCALE QUARK FLUX MODEL

Mathematical Continuity Model of Quark Flux

This model expresses how flux conservation and transformation propagate across scales — from quark interactions to atomic and molecular systems.

1. Continuity Equation at the Quark Scale

At the fundamental level, flux conservation follows:

$$\partial_{\mu} J^{\mu}_{\text{total}} = 0$$

where

$$J^{\mu}_{\text{total}} = \alpha_{\text{QCD}} J^{\mu}_{\text{QCD}} + \alpha_{\text{QED}} J^{\mu}_{\text{QED}} + \alpha_{\text{Weak}} J^{\mu}_{\text{Weak}} + \alpha_{\text{Gravity}} J^{\mu}_{\text{Gravity}}$$

This ensures that the total quark flux is divergence-free — energy and momentum are conserved across all interactions.

2. Transition to Hadron Scale

Integrate over the confinement volume V_H :

$$\int_{V_H} \partial_{\mu} J^{\mu}_{\text{total}} dV = 0$$

This yields effective hadron parameters:

$$M_H = \int_{V_H} \rho_{\text{flux}}(r) d^3r, \mu_H = \int_{V_H} \mathbf{r} \times \mathbf{J}^{\text{QED}} d^3r$$

These act as boundary conditions for the atomic-scale continuity.

3. Atomic Scale Continuity

At the atomic level, flux transitions into electromagnetic field continuity:

$$\nabla \cdot \mathbf{E} = \rho_{\text{QED}} \epsilon_0, \nabla \times \mathbf{B} = \mu_0 \mathbf{J}^{\text{QED}} + \mu_0 \epsilon_0 \partial \mathbf{E} / \partial t$$

The hadron magnetic moment μ_H modifies local field distributions, influencing atomic energy levels.

Mathematical Continuity Model QUARK FLUX

Mathematical Continuity Model of Quark Flux

4. Molecular Scale Continuity

Flux coupling between atoms is expressed as:

$$\nabla \cdot \mathbf{J}_{\text{molecular}} = -\partial p_{\text{bond}} / \partial t$$

where p_{bond} represents the flux density associated with chemical bonding — an emergent property derived from atomic flux overlap.

5. Unified Continuity Condition

Across all scales:

$$\partial \mu J_{\text{quark}} \rightarrow \partial \mu J_{\text{hadron}} \rightarrow \partial \mu J_{\text{atomic}} \rightarrow \partial \mu J_{\text{molecular}} = 0$$

This expresses flux continuity from quark confinement to molecular interaction — a seamless conservation law through hierarchical domains.

Interpretation

- Quark flux defines the microscopic source terms.
- Hadron flux integrates confinement effects.
- Atomic flux translates into electromagnetic continuity.
- Molecular flux emerges from overlapping atomic flux fields.

Together, they form a continuous flux hierarchy, preserving energy and momentum from the smallest to the largest quantum scales.

Theoretical Simulation Outline

⚙️ Quark Flux Continuity Simulation Outline

1. Initialization

- Define constants: $g_s, e, g_W, \kappa, \alpha_i, \beta_i, \gamma_i$
- Set grid: 4D lattice (space + time)
- Boundary conditions: confinement radius for quarks, atomic radius for electrons

2. Flux Field Setup

For each lattice point x :

$$J_i\mu(x) = \text{interaction strength} \times \text{field operator}$$

Compute:

- $JQCD\mu$ for gluon fields
- $JQED\mu$ for photon fields
- $JWeak\mu$ for W/Z exchange
- $JGravity\mu$ for curvature coupling

3. Continuity Enforcement

Apply discrete conservation:

$$J\mu(x+\Delta x) - J\mu(x)\Delta x = 0$$

This ensures flux conservation across the grid.

4. Scale Transition

- Quark $\rightarrow$ Hadron: integrate flux density over confinement volume
- Hadron $\rightarrow$ Atomic: translate magnetic and mass parameters into electromagnetic potentials
- Atomic $\rightarrow$ Molecular: compute overlap of atomic flux fields for bonding

5. Numerical Integration

Use finite-difference or lattice Monte Carlo methods:

$$MH = \sum x p \text{flux}(x) \Delta V$$
$$\Gamma H = \sum t \mid JWeak\mu(t) \mid 2\Delta t$$

6. Output and Validation

- Compare simulated hadron masses, magnetic moments, and decay rates with experimental data.
- Adjust coefficients iteratively using gradient descent or Bayesian optimization.

7. Cross-Scale Coupling

Ensure continuity:

$$\partial\mu J_{quark}\mu = \partial\mu J_{hadron}\mu = \partial\mu J_{atomic}\mu = \partial\mu J_{molecular}\mu = 0$$

This maintains flux conservation across all scales.

This outline gives you a roadmap for coding the simulation — from initializing flux fields to validating results.

QUARK FLUX CONTINUITY

Computational Continuity Simulation Outline

1. Initialization

- Define constants:
 - Coupling strengths g_s, e, g_W, κ
 - Weighting coefficients $\alpha_i, \beta_i, \gamma_i$
- Set up a 4D lattice grid (space + time).
- Choose boundary conditions: confinement radius for quarks, atomic radius for electrons.

2. Flux Field Construction

At each lattice point x :

$$J_{\mu}(x) = \text{interaction strength} \times \text{field operator}$$

Compute:

- $J_{QCD\mu} \rightarrow$ gluon flux
- $J_{QED\mu} \rightarrow$ photon flux
- $J_{Weak\mu} \rightarrow$ W/Z boson flux
- $J_{Gravity\mu} \rightarrow$ energy-momentum tensor flux

3. Continuity Enforcement

Apply discrete conservation law:

$$J_{\mu}(x+\Delta x) - J_{\mu}(x)\Delta x = 0$$

This ensures flux conservation across the grid.

4. Scale Transition

- Quark $\rightarrow$ Hadron: integrate flux density over confinement volume.
- Hadron $\rightarrow$ Atomic: translate hadron mass and magnetic moment into electromagnetic potentials.
- Atomic $\rightarrow$ Molecular: compute overlap of atomic flux fields to model bonding.

5. Numerical Integration

- Mass:
$$M_H = \sum x \rho_{\text{flux}}(x) \Delta V$$
- Magnetic Moment: extract rotational components via Fourier transforms.
- Decay Rate:

$$\Gamma_H = \sum_t |J_{Weak\mu}(t)|^2 \Delta t$$

6. Validation

- Compare simulated hadron masses, magnetic moments, and decay rates with experimental data.
- Adjust coefficients iteratively using optimization methods (gradient descent, Bayesian fitting).

7. Cross-Scale Continuity

Ensure conservation across all domains:

$$\partial_{\mu} J_{\text{quark}\mu} = \partial_{\mu} J_{\text{hadron}\mu} = \partial_{\mu} J_{\text{atomic}\mu} = \partial_{\mu} J_{\text{molecular}\mu} = 0$$

Next Step

This outline is ready to be turned into pseudo-code (Python-style or Mathematica) for actual implementation. It would show loops over lattice points, flux updates, and integration routines.

QUARK FLUX CONTINUITY

visualization of the Mathematical Continuity Model of Quark Flux

What the Diagram Shows

- **Quark Scale:** Unified flux equation ensuring conservation at the fundamental level.
- **Hadron Scale:** Integration over confinement volume gives hadron mass and magnetic moment.
- **Atomic Scale:** Electromagnetic continuity equations (Maxwell's laws) emerge from quark flux contributions.
- **Molecular Scale:** Bonding flux continuity describes chemical interactions.
- **Unified Continuity Condition:** A seamless conservation law across all scales, ensuring energy and momentum flow consistently from quarks to molecules.

This makes the abstract math tangible — you can see how each layer builds on the previous one, forming a continuous hierarchy of flux.

Mathematical Continuity Model of Quark Flux

Flux Conservation from Quarks to Molecules

Quark Scale. Quark Flux Dynamics

$$\partial_\mu J^\mu_{\text{total}} = 0$$

$$J^\mu_{\text{total}} = a_{\text{QCD}} J^\mu_{\text{QCD}} + a_{\text{QED}} J^\mu_{\text{QED}} + a_{\text{Weak}} J^\mu_{\text{Weak}} + a_{\text{Gravity}}$$

Hadron Scale. Confinement Integration

$$M_H = \int_{V_L} \bar{F}_{lux}(z) d^3r$$

$$\bar{\mu}_H = \int_{V_H} \bar{H}_j r \times J^\mu_{\text{QED}} d^3r$$

Atomic Scale. Electromagnetic Continuity

$$\nabla \cdot E = \hat{p}_{(QED)}$$

$$\nabla \times 0 = \mu_0 \hat{J}_{QED} + \mu_0 0 \frac{\partial E}{\partial t}$$

Molecular Scale. Chemical Bond Flux

$$\nabla \cdot J_{\text{molecular}} = - \frac{\mathcal{L}p}{e_{\text{bond}}} / \delta t$$

Unified Continuity Condition

$$\partial_\mu J^\mu_{\text{-quark}} \rightarrow \partial_\mu J^\mu_{\text{-hadron}} \rightarrow \partial_\mu J^\mu_{\text{-atomic}} \rightarrow \partial_\mu J^\mu_{\text{-molecular}} = 0$$

CENTRIFUGE FORCE EQUATIONS

Centrifugal force is the apparent outward force experienced by an object moving in a circular path. It is equal in magnitude and opposite in direction to the centripetal force.

Core Formula

The standard equation for centrifugal force is:

$$F_c = m \cdot a_c = m \cdot v^2 / r$$

Where:

- F_c = Centrifugal force (Newtons, N)
- m = Mass of the object (kilograms, kg)
- v = Tangential velocity (meters per second, m/s)
- r = Radius of the circular path or distance from the rotation axis (meters, m)

Alternative Formulations

- **Angular Velocity Form:** Expressed in terms of angular velocity (ω , measured in rad/s), where $v = \omega \cdot r$:

$$F_c = m \cdot \omega^2 \cdot r$$

- **Rotational Speed Form (RPM):** Expressed using rotational speed (n , in revolutions per minute):

$$F_c = m \cdot r \cdot (60 \cdot 2\pi \cdot n / 60)^2 \approx 0.01097 \cdot m \cdot r \cdot n^2$$

Relative Centrifugal Force (RCF / g-Force)

In laboratory centrifuges, force is usually expressed in multiples of Earth's gravitational acceleration ($g \approx 9.81 \text{ m/s}^2$), known as Relative Centrifugal Force (RCF):

$$RCF = g \cdot \omega^2 / g \approx 1.118 \times 10^{-5} \cdot r_{cm} \cdot (RPM)^2$$

- r_{cm} = Rotational radius in centimeters (cm)
- RPM = Rotational speed in revolutions per minute

outward apparent directives
CENTRIFUGE EQUATIONS

RELATIVE CENTRIFUGAL FORCE

details on aspects and components

Relative Centrifugal Force (RCF), often designated as $\times g$ or g -force, is a dimensionless ratio comparing the radial acceleration generated inside a spinning centrifuge rotor to Earth's standard gravitational acceleration ($g \approx 9.80665 \text{ m/s}^2$).

While **RPM** (revolutions per minute) measures rotational speed, **RCF** quantifies the actual force exerted on samples and serves as the universal standard for reproducing protocols across different centrifuges.

Centrune Speed Interactive Calculator

Sample experiences
 $\text{RCF} = \omega^2 r / g$

STANDARD FORMULA

Relative Centrifugal Force

Key Mathematical Components

The standard formula for calculating RCF is derived by dividing centripetal acceleration ($a_c = \omega^2 r$) by standard gravitational acceleration (g):

$$\text{RCF} = \frac{\omega^2 \cdot r}{g} = \frac{\left(\frac{2\pi \cdot \text{RPM}}{60}\right)^2 \cdot r}{9.80665} \approx 1.118 \times 10^{-5} \cdot r_{\text{cm}} \cdot (\text{RPM})^2$$

1. **Rotational Speed Component (RPM²):** RCF scales exponentially with the square of the speed. Doubling the RPM quadruples the centrifugal force acting on the sample.
2. **Radial Distance Component (r):** RCF scales linearly with distance from the axis of rotation. Because r varies along the length of a sample tube, RCF changes continuously from top to bottom.
3. **Gravitational Constant (g):** Normalizes the force into multiples of standard gravity ($1 \times g = 9.80665 \text{ m/s}^2$).

The rules at Animal kingdoms in the Reservations Wildlife cannot ever be govern by human. They stood for their own being. Each days many species are being more prone to the attack of human greeds whom after their beauties.

For the reasons to make it more lasts, it is the human factors that must be kept in the normative manners. Each of the planned journey near the wildlife reservations areas must be monitored carefully. No risky tresspassing can ever allowed. Its not only for the safety of the animals, but also for averasing the danger of animal responsive defense reactions towards every human entering their natural living habitat.

MAGNETIC CENTRIFUGE MULTI ROTATOR ENGINES

*from these concepts ;

A magnetic centrifuge multi-rotator engine is an advanced propulsion or fluid-dynamics concept that merges magnetic levitation/drive mechanisms, multi-stage concentric or planetary centrifuges, and viscous fluid coupling.

Core Architecture & Operating Principles

MAGNETIC CENTRIFUGE MULTI ROTATOR ENGINES

*from these concepts ;
centrifuge components*

A magnetic centrifuge multi-rotator engine is an advanced propulsion or fluid-dynamics concept that merges magnetic levitation/drive mechanisms, multi-stage concentric or planetary centrifuges, and viscous fluid coupling.

1. Magnetic Integration (Drive & Levitation)

- **Direct Electromagnetic Drive:** Replaces mechanical drive motors by embedding permanent magnets into the rotor assemblies and using outer electromagnetic stators (similar to a brushless DC motor or active magnetic bearing array).
- **Frictionless Magnetic Bearings:** Replaces mechanical bearings and lubrication systems with Active Magnetic Bearings (AMBs). This eliminates mechanical drag, wear, and heat generation at high rotational speeds.

2. Multi-Rotator Configuration

- **Counter-Rotating Dual/Multi Rotors:** Multiple nested or coaxially arranged rotors spin in opposite directions or at differential speeds ($\Delta\omega = \omega_1 - \omega_2$).
- **Planetary Centrifuge Modules:** Smaller peripheral rotor buckets rotate on their own axes while revolving around a central spindle, multiplying local g -forces for enhanced separation or fluid acceleration.

MAGNETIC CENTRIFUGE MULTI ROTATOR ENGINES

*from these concepts ;
centrifuge components*

A magnetic centrifuge multi-rotator engine is an advanced propulsion or fluid-dynamics concept that merges magnetic levitation/drive mechanisms, multi-stage concentric or planetary centrifuges, and viscous fluid coupling.

Fluid Dynamics & Viscosity Dynamics

The engine leverages fluid shear and centrifugal force to create thrust, heat, or energy separation.

Shear Stress & Dynamic Viscosity

Inside the inter-rotor gaps, shear stress (τ) is generated according to Newton's Law of Viscosity:

$$\tau = \eta \cdot \frac{dV}{dY}$$

- η : Dynamic viscosity (Pa · s)
- $\frac{dV}{dY}$: Velocity gradient across the gap (s⁻¹)

In counter-rotating nested rotors with radii r_1 and r_2 and angular velocities ω_1 and $-\omega_2$, the relative shear rate increases significantly:

$$\frac{dV}{dY} \approx \frac{r_1\omega_1 - (-r_2\omega_2)}{r_2 - r_1}$$

MAGNETIC CENTRIFUGE MULTI ROTATOR ENGINES

*from these concepts ;
centrifuge components*

A magnetic centrifuge multi-rotator engine is an advanced propulsion or fluid-dynamics concept that merges magnetic levitation/drive mechanisms, multi-stage concentric or planetary centrifuges, and viscous fluid coupling.

Sedimentation & Mass Separation

As fluid passes through the multi-rotator, suspended particles or heavier fluid fractions experience Relative Centrifugal Force (RCF):

$$\text{RCF} = 1.118 \times 10^{-5} \cdot r \cdot (\text{rpm})^2$$

Sedimentation velocity (v) follows Stokes' Law under centrifugal force:

$$v = \frac{d^2(\rho_s - \rho_l) \cdot \omega^2 r}{18\eta}$$

- **Viscosity Thermal Thinning:** High shear rates and centrifugal friction increase fluid temperature, reducing dynamic viscosity (η). Lower viscosity accelerates particle drift velocity (v), increasing operational efficiency.

MAGNETIC CENTRIFUGE MULTI ROTATOR ENGINES

*from these concepts ;
centrifuge components*

A magnetic centrifuge multi-rotator engine is an advanced propulsion or fluid-dynamics concept that merges magnetic levitation/drive mechanisms, multi-stage concentric or planetary centrifuges, and viscous fluid coupling.

Concept Comparison Table

Feature / Dimension	Standard Centrifuge	Magnetic Multi-Rotator Engine
Drive Mechanism	Mechanical motor & spindle	Integrated electromagnetic stator array
Bearings	Mechanical ball/roller bearings	Active magnetic bearings (contactless)
Rotator Setup	Single rotor (Fixed/Swinging)	Coaxial nested or planetary multi-rotors

Primary Limits	Bearing wear, mechanical friction	Thermal dissipation, magnetic saturation

MAGNETIC CENTRIFUGE MULTI ROTATOR ENGINES

*from these concepts ;
centrifuge components*

A magnetic centrifuge multi-rotator engine is an advanced propulsion or fluid-dynamics concept that merges magnetic levitation/drive mechanisms, multi-stage concentric or planetary centrifuges, and viscous fluid coupling.

Key Engineering Challenges

- **Gyroscopic & Rotordynamic Instability:** Multi-axis or counter-rotating high-mass rotors produce severe precessional forces. Real-time active magnetic positioning algorithms are required.
- **Thermal Viscosity Control:** Because viscosity drops as temperature rises, active cooling or thermal management is necessary to maintain required fluid shear or buoyancy forces.
- **Magnetic Shielding:** High electromagnetic fields driving the rotors must be shielded to prevent interference with sensitive flow meters or external control sensors.

ROTORDYNAMIC INSTABILITY

*from these concepts ;
centrifuge components*

Rotordynamic instability occurs when non-conservative cross-coupled forces transfer rotational energy from a rotor's spin into lateral whirling motion.

Unlike forced response (e.g., mass unbalance), rotordynamic instability is a self-excited vibration that grows exponentially once the rotor exceeds a threshold speed, governed by negative effective damping.

1. Primary Aspects of Rotordynamic Instability

Rotordynamic stability analysis evaluates the interaction between physical instability mechanisms and system dynamics:

- **Fluid Film Forces (Oil Whirl & Whip):** Fluid film hydrodynamic bearings generate asymmetric pressure distributions. The cross-coupled stiffness ($K_{xy} \neq K_{yx}$) acts as a destabilizing tangential force perpendicular to shaft deflection.
- **Internal Material Damping (Hysteresis):** Rotating damping inside the shaft material or at shrink-fit interfaces causes a phase lag between shaft bending and stress response, inducing forward whirl above the first critical speed.
- **Aerodynamic Cross-Coupling (Alford Force):** In turbomachinery, non-uniform blade clearance causes asymmetric thermodynamic work across the circumference, driving lateral forces on impellers and turbines.
- **Gyroscopic & Asymmetric Stiffness Coupling:** High polar-to-transverse inertia ratios (I_p/I_t) split critical speeds into forward and backward precession modes, modifying stability boundaries.

ROTORDYNAMIC INSTABILITY

*from these concepts ;
centrifuge components*

Rotordynamic instability occurs when non-conservative cross-coupled forces transfer rotational energy from a rotor's spin into lateral whirling motion.

Unlike forced response (e.g., mass unbalance), rotordynamic instability is a self-excited vibration that grows exponentially once the rotor exceeds a threshold speed, governed by negative effective damping.

2. Core Equations Governing Rotordynamics

A. General Equation of Motion (4-DOF Rotor System)

The discretized linearized equation of motion in stationary coordinates is expressed as:

$$\mathbf{M}\ddot{\mathbf{q}}(t) + (\mathbf{C} + \Omega\mathbf{G})\dot{\mathbf{q}}(t) + (\mathbf{K} + \mathbf{K}_c(\Omega))\mathbf{q}(t) = \mathbf{F}_{ext}(t)$$

where:

- $\mathbf{M}$ is the symmetric mass matrix.
- $\mathbf{C}$ is the symmetric physical damping matrix.
- $\mathbf{G}$ is the skew-symmetric gyroscopic matrix ($\mathbf{G}^T = -\mathbf{G}$).
- $\mathbf{K}$ is the symmetric structural stiffness matrix.
- $\mathbf{K}_c$ is the asymmetric cross-coupled stiffness matrix ($\mathbf{K}_c^T \neq \mathbf{K}_c$).
- Ω is the rotor spin speed (rad/s).
- $\mathbf{q}(t) = [x, y, \theta_x, \theta_y]^T$ is the generalized displacement vector.

ROTORDYNAMIC INSTABILITY

*from these concepts ;
centrifuge components*

B. Fluid Film Bearing Forces & Instability (Oil Whirl / Whip)

Hydrodynamic bearing forces are linearized using 8×8 dynamic coefficients (4 stiffness, 4 damping):

$$\begin{bmatrix} F_x \\ F_y \end{bmatrix} = - \begin{bmatrix} K_{xx} & K_{xy} \\ K_{yx} & K_{yy} \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} - \begin{bmatrix} C_{xx} & C_{xy} \\ C_{yx} & C_{yy} \end{bmatrix} \begin{bmatrix} \dot{x} \\ \dot{y} \end{bmatrix}$$

For a symmetric bearing model where $K_{xx} = K_{yy} = K$, $C_{xx} = C_{yy} = C$, $K_{xy} = k$, and $K_{yx} = -k$:

1. Threshold Speed of Instability (Ω_{st}):

The threshold speed where whirl frequency ratio (WFR) triggers instability is given by:

$$\Omega_{st} = \frac{\omega_n}{\text{WFR}} \approx 2\sqrt{\frac{K}{m}}$$

(For classic hydrodynamic journal bearings, $\text{WFR} \approx 0.48 - 0.50$, leading to oil whirl at roughly $2 \times$ the first natural frequency ω_n).

2. Whirl Energy Rate (Work Per Cycle):

The net energy input E_{cycle} imparted to the rotor orbit of radius R per cycle by cross-coupling stiffness k versus direct damping C is:

$$E_{cycle} = \pi R^2 (k - \omega C_{xx})$$

If $k > \omega C_{xx}$, energy is continuously added to the rotor orbit, causing unbounded exponential amplitude growth.

ROTORDYNAMIC INSTABILITY

*from these concepts ;
centrifuge components*

C. Internal Damping Instability Equation

For a rotor with internal rotating damping C_i and stationary external damping C_e , the lateral force vector in rotating coordinates transformed back to fixed reference frame yields:

$$\mathbf{F}_{int} = -C_i \begin{bmatrix} \dot{x} + \Omega y \\ \dot{y} - \Omega x \end{bmatrix}$$

This generates a destabilizing cross-coupled force $k_{int} = C_i \Omega$. The system becomes unstable when the spin speed satisfies:

$$\Omega > \omega_n \left(1 + \frac{C_e}{C_i} \right)$$

ROTORDYNAMIC INSTABILITY

*from these concepts ;
centrifuge components*

D. Aerodynamic Cross-Coupling (Alford's Force)

In axial turbines and compressors, blade tip clearance variation $\Delta\beta$ generates an aerodynamic cross-coupling force F_t :

$$F_t = \frac{\beta \cdot T}{D \cdot H} \cdot y$$

$$\mathbf{K}_{\text{aerodynamic}} = \begin{bmatrix} 0 & Q \\ -Q & 0 \end{bmatrix}, \quad \text{where } Q = \frac{\beta \cdot T}{D \cdot H}$$

where:

- T is the stage torque.
- D is the rotor pitch diameter.
- H is the blade height.
- β is Alford's efficiency factor parameter.
- Q is the cross-coupled aerodynamic stiffness parameter.

ROTOR DYNAMIC INSTABILITY

E. Eigenvalue Analysis & Stability Criteria

To determine absolute stability, substitute state-space solution $\mathbf{q}(t) = \hat{\mathbf{q}}e^{st}$ into the homogeneous equation of motion to solve the complex eigenvalue problem:

$$\det \left(s^2 \mathbf{M} + s(\mathbf{C} + \Omega \mathbf{G}) + (\mathbf{K} + \mathbf{K}_c) \right) = 0$$

The complex roots are $s_j = \lambda_j + i\omega_j$, where λ_j is the decay rate and ω_j is the damped natural frequency.

1. Logarithmic Decrement (δ):

$$\delta = \frac{-2\pi\lambda_j}{|\omega_j|}$$

- Stable System: $\lambda_j < 0 \implies \delta > 0$
- Threshold Speed: $\lambda_j = 0 \implies \delta = 0$
- Unstable System: $\lambda_j > 0 \implies \delta < 0$

ROTOR DYNAMIC INSTABILITY

Instability Type	Primary Driver	Key Parameter / Threshold	Mitigation Technique
Oil Whirl	Hydrodynamic wedge fluid shear	$\Omega \approx 2\omega_n$	Tilt-pad journal bearings, anti-whirl profiles
Oil Whip	Fluid force locked to 1st critical speed	$\Omega \geq 2\omega_n$ (locked to ω_n)	Increase bearing direct damping C_{xx}
Internal Friction	Shaft material or shrink-fit lag	$\Omega > \omega_n(1 + C_e/C_i)$	Flexibly mounted bearing supports, stress isolation
Alford Effect	Non-uniform blade clearance torque	Cross-coupled stiffness Q	Swirl brakes, damper seals (labyrinth/honeycomb)

ANTI MAGNETIC PHONON SHIELDING

Building an "anti-magnetic" shield for a space vehicle using dense exterior layers of phonon shielding involves a multi-physics approach known as magneto-acoustic and electro-phonon decoupling.

Phonons are quanta of mechanical/lattice vibrations (acoustic waves and heat), while magnetic fields are electromagnetic forces.

To use phonons to mitigate magnetic interference, induction heating, or magnetohydrodynamic (MHD) plasma forces during spaceflight, the shield relies on phononic crystals (PnCs) and piezoelectric or magnetostrictive metamaterials.

STEP-BY-STEP TECHNICAL FRAMEWORK TO ENGINEER THIS SYSTEM

PHASE 1: MATERIAL & STRUCTURAL ARCHITECTURE

THE SHIELD IS ARRANGED IN A MULTI-LAYERED FUNCTIONAL STACK ON THE HULL EXTERIOR, PROGRESSING FROM THE OUTER VACUUM INTERFACE INWARD TO THE SPACECRAFT SUPERSTRUCTURE:

[OUTER SPACE ENVIRONMENT]

—— LAYER 1: PIEZO-ELECTRIC METAMATERIAL (MAGNETIC-TO-PHONON TRANSDUCER)

—— LAYER 2: ULTRA-DENSE ACOUSTIC/PHONONIC BANDGAP SUPERLATTICE (PNC)

—— LAYER 3: PHONONIC-THERMAL HEAT SINK / THERMOELECTRIC HARVESTER

—— LAYER 4: HIGH-PERMEABILITY CRYOGENIC SUPERCONDUCTOR (PASSIVE MAGNETIC CORE)

[SPACECRAFT INNER HULL]

ANTI MAGNETIC PHONON SHIELDING

Layer 1: The Transducer Surface (Magnetic-to-Phonon Conversion)

- **Components:** Ferrimagnetic or magnetostrictive materials (e.g., Terfenol-D) paired with piezoelectric ceramics (e.g., Lead Zirconate Titanate or Barium Titanate).
- **Mechanism:** When incoming magnetic field lines fluctuate against the hull (or during re-entry MHD interaction), the magnetostrictive layer experiences physical strain. This converts incoming magnetic energy into coherent vibrational phonons within the lattice instead of allowing magnetic flux to penetrate.

Layer 2: Dense Phononic Crystal Superlattice (Phonon Trap)

- **Components:** Alternating sub-nanometer layers of high-density and low-density materials (e.g., Tungsten (\$W\$) and Silicon (\$Si\$), or Graphene/Titanium-Nitride superlattices).
- **Mechanism:**
 - a. Bragg scattering and local resonances create Phononic Bandgaps (PBGs).
 - b. The generated phonons are reflected, redirected along the hull surface, or trapped in localized defect modes.
 - c. This prevents the mechanical vibration and eddy currents from penetrating into the primary hull.

ANTI MAGNETIC PHONON SHIELDING

Phase 2: Electro-Phononic Decoupling Mechanism

To counteract static and low-frequency magnetic fields using phonons:

- **Active Phonon Injection:** Electro-acoustic transducers inject high-frequency phonons (hypersonic frequencies, GHz to THz) into the outer metamaterial matrix.
- **Lattice Distortion:** High-amplitude, coherent acoustic phonons cause rapid periodic deformation of the solid crystal lattice.
- **Spin-Phonon Coupling Suppression:** The lattice deformation disrupts the spin-orbit interactions and magnetic domain realignments within the shield's magnetic-responsive layers.
- This dynamically suppresses the magnetic permeability (μ) of the outer shell, causing the magnetic flux lines to bend around the craft (a magnetic cloaking effect).

Phase 3: Energy Dissipation & Harvesting

The phonons generated by blocking the magnetic field represent trapped kinetic and vibrational energy. If unmanaged, this turns into extreme heat.

- **Phonon Waveguides:** Channel trapped high-frequency phonons along the perimeter of the hull using topological phononic edge-states.
- **Thermoelectric Conversion:** Route the phonon energy toward thermoelectric arrays (e.g., Bismuth Telluride layers) to convert vibrational and thermal energy back into auxiliary DC power for the vehicle's onboard systems.

ANTI MAGNETIC PHONON SHIELDING

Summary Checklist for Engineering Design

Layer	Primary Function	Materials Used
1. Transducer Shell	Converts magnetic energy into mechanical phonons	Terfenol-D / PZT Piezoelectric Composites
2. Phononic Bandgap	Blocks and redirects acoustic/phonon propagation	Alternating Tungsten/Silicon Superlattices
3. Topological Waveguide	Routes phonons to heat sinks away from crew quarters	Engineered Acoustic Metamaterials
4. Thermoelectric Harvester	Converts dissipated phonon heat into electrical power	Bi_2Te_3 / Thermoelectric Meta-devices

Anti-Magnetic Phonon Shielding Engine Design

Space Vehicle's Exterior

QUANTUM FIELD

Lattice of The Phonon Engines

how quantum field stabilization channels zero-point energy into the phonon lattice of the phonon engine for a stellar journey. This step-by-step guide shows the technical flow and stabilization process:

Initialize Quantum Field

Setup

Stabilize the quantum vacuum to prepare zero-point energy extraction.

- Align superconducting magnetic rings
- Establish quantum coherence zones
- Monitor vacuum fluctuation amplitudes

Extract Zero-Point Energy

Critical

Draw energy from vacuum fluctuations into controlled channels.

$$E_{\text{ZPE}} = \frac{1}{2} \hbar \omega$$

- Use quantum harmonic oscillators
- Capture fluctuation spikes via resonance
- Regulate flow with photon feedback loops

Feed Energy into Phonon Lattice

Conversion

Channel zero-point energy into the phonon lattice for usable power.

- Direct energy beams into crystal lattice
- Excite phonon vibrational modes
- Balance heat dissipation with acoustic recycling

Stabilize Engine Output

Safety

Ensure lattice oscillations remain coherent for propulsion stability.

- Apply photon-phonon coupling feedback
- Monitor resonance frequencies
- Adjust damping coefficients to prevent runaway oscillations

This process highlights how quantum stabilization ensures a continuous feed of zero-point energy into the phonon lattice, transforming vacuum fluctuations into structured vibrational energy that powers the phonon engine. It's essentially a bridge between the quantum vacuum and macroscopic propulsion stability.
